

The open hearth furnace gets <sup>its</sup> name from the fact <sup>that</sup> the charge is open at the surface and is exposed to the flame which shoots across it. The furnace is a very large brick structure <sup>fu</sup> which has a shallow hearth with a very large area. It works on the regenerative principle, <sup>giving</sup> means that the products of combustion are recycled to assist in the heating process. One <sup>of</sup> side <sup>of</sup> the <sup>+</sup> structure, air is preheated in checker chambers before it is combined with the fuel which is also preheated. On the other side, the chambers were preheated by the products of combustion. <sup>the</sup> flow is reversed once <sup>every</sup> twenty minutes. The charge can be solid or molten and consist of pig iron or scapy and flux. Most often, the <sup>charge</sup> is molten pig direct from the blast furnace as this saves heating <sup>costs</sup>. As compared to the Bessemer furnace, the open hearth furnace is slow (eg, 8-10 hours) because the air-fuel <sup>mixture</sup> must be preheated and the open-hearth furnace is an indirect <sup>oxidation</sup> process whereas the Bessemer is direct. However, the <sup>open</sup> hearth furnace has much <sup>greater</sup> capacity, is more accurate, and can handle pig iron with a very high phosphorous <sup>content</sup>. <sup>the</sup> majority of American ores are high in phosphorous. Open hearth furnaces, depending on <sup>their</sup> ~~there~~ size, will produce from one hundred and <sup>twenty</sup>-five to five hundred and fifty tons.
